ABSTRACT

Objective: Prior research suggests an acutely elevated risk of myocardial infarction and sudden cardiac death in the hour after coffee intake. However, the risk of ischemic stroke associated with transient exposure to coffee remains unclear. We hypothesized that caffeine intake is associated with a transiently increased risk of ischemic stroke.

Methods: In this multicenter case-crossover study, we interviewed 390 subjects (209 men, 181 women) between January 2001 and November 2006 a median of 3 days after acute ischemic stroke. Each subject's coffee consumption in the hour before stroke symptoms was compared with his or her usual frequency of consumption in the prior year.

Results: Of the 390 subjects, 304 (78%) drank coffee in the prior year, 232 within 24 hours and 35 within 1 hour of stroke onset. The relative risk (RR) of stroke in the hour after consuming coffee was 2.0 (95% confidence interval [CI], 1.4–2.8; p < 0.001). There was no apparent increase in risk in the hour following consumption of caffeinated tea (RR = 0.9, 95% CI 0.4–2.0; p = 0.85) or cola (RR = 1.0, 95% CI 0.4–2.4; p = 0.95). The association between ischemic stroke in the hour after coffee consumption was only apparent among those consuming 1 cup per day but not for patients who consumed coffee more regularly (p for trend = 0.002). Relative risks remained similar when the sample was restricted to those who were not simultaneously exposed to other potential triggers and the results remained significant after stratifying by time of day.

Conclusion: Coffee consumption transiently increases the risk of ischemic stroke onset, particularly among infrequent drinkers. Neurology® 2010;75:1583–1588

GLOSSARY
CI = confidence interval; MI = myocardial infarction; RR = relative risk; TOAST = Trial of Org 10172 in Acute Stroke Treatment.

Approximately 795,000 new or recurrent cases of stroke occur each year. Cerebrovascular disease is a leading cause of serious, long-term disability in the United States and it is the third leading cause of mortality, accounting for approximately 1 of every 17 deaths in the United States in 2005. The estimated direct and indirect cost of stroke for 2009 is $68.9 billion.1

Coffee has been documented to have acute deleterious physiologic effects within hours after consumption, including elevated levels of (nor)epinephrine,2 increased systolic and diastolic blood pressure3 and vascular resistance,4 and a slight drop in heart rate.3 Compared to decaffeinated coffee, consumption of caffeinated coffee acutely increases arterial stiffness5,6 and impairs endothelium-dependent vasodilation.7 Caffeine has also been shown to eliminate the protective effect of ischemic preconditioning.8 There is evidence of an acutely elevated risk of acute myocardial infarction9 and sudden cardiac death10 in the hour after coffee intake, but to our knowledge, there has not been any research to examine the risk of ischemic stroke associated with transient exposure to caffeine and whether the risk varies by the sources of caffeine.
Our primary objective was to examine the association between caffeinated coffee consumption and the risk of acute ischemic stroke in the subsequent hour.

**METHODS Study design.** The Stroke Onset Study used a case-crossover design, a variation of a case-control design that is appropriate when a brief exposure (caffeinated coffee consumption) causes a transient change in the risk of an acute outcome (ischemic stroke). We compared a subject’s coffee consumption in the hour prior to onset of stroke symptoms (the case period) with the same subject’s usual frequency of coffee consumption in the prior year (the control period). Because control information for each subject is based on his or her own past exposure experience, self-matching eliminates confounding by risk factors that are constant within individuals over the sampling period but often differ between study subjects.

**Study population.** The Stroke Onset Study was conducted in 3 medical centers (Beth Israel Deaconess Medical Center, Boston, MA; University of North Carolina Hospitals, Chapel Hill, NC; Vancouver Island Health Authority, Victoria, BC) between January 2001 and November 2006. Trained research staff identified eligible subjects by reviewing admission logs and charts of subjects admitted to each hospital’s stroke service. Additionally, subjects with new onset of an acute neurologic syndrome compatible with stroke were screened upon admission to emergency departments. Presumed stroke etiology was determined according to an abbreviated Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification system. Across all sites, 43% of patients with confirmed ischemic stroke met all inclusion criteria. Of these, 83% agreed to participate, 5.5% refused, and the remaining 12.5% were discharged from the hospital before the interviewers were able to approach them. The final sample includes 390 subjects (209 men and 181 women) who were interviewed a median of 3 days (range 0–14) after sustaining an acute ischemic stroke.

For each case, trained study personnel using standardized abstraction forms recorded data on demographics, medical history, and admission laboratory results. To be eligible, subjects were required to have a neurologist-confirmed diagnosis of acute ischemic stroke, either by clinical diagnosis or appropriate imaging studies, to be English-speaking, and to be free of dementia prior to the index event. Subjects were excluded if they were unable to complete the structured interview because they were cognitively impaired, had poor memory around the time of the stroke, could not identify the time of onset of their stroke symptoms, experienced aphasia, or were too ill to complete the structured interview that lasted 30 to 45 minutes.

**Coffee consumption.** Interviewers used a structured questionnaire and asked subjects if they had consumed any coffee in the year preceding their stroke. Subjects who reported any coffee consumption were also asked to report the last time that they had consumed a serving of coffee and their usual frequency of coffee consumption over the prior year. The portion size for 1 serving of coffee was defined as 8 ounces or 1 cup of caffeinated coffee. Similar questions were asked about consumption of decaffeinated tea and cola. Subjects were also asked to report the timing of their last exposure to other potential triggers and usual frequency of these factors in the year preceding the onset of stroke symptoms. Other information collected from the interview included medication use and symptoms on the day of the stroke.

**RESULTS** The characteristics of the Stroke Onset Study subjects are presented in the table. Of the 390 subjects with acute ischemic stroke who were interviewed, 305 (78%) reported that they had consumed...
One subject provided no information about usual coffee intake, so the subject was excluded from all analyses. Compared to non-drinkers, subjects who reported coffee consumption within the past year were more likely to be current smokers and they were less likely to have a history of atrial fibrillation. Among the 304 subjects who drank coffee in the prior year, 249 (82%) drank at least 1 serving per day, 35 (12%) drank at least once per week, 13 (4%) drank coffee at least once per month, and 7 (2%) drank coffee less than once per month; the median frequency of consumption was 7 times per week. Thus, the average amount of person-time exposed to coffee in the prior year (the control period) was 364 hours per subject.

Among the 304 subjects who drank coffee in the prior year, 35 subjects consumed at least 1 serving of coffee within 1 hour of the onset of stroke symptoms (the case period). We found that within 1 hour after coffee consumption, the risk of stroke onset was 2.0-fold higher (95% CI 1.4–2.8; \( p < 0.001 \)) compared with periods of nonuse, and it rapidly returned to baseline thereafter. The risks of ischemic stroke in the hour following consumption of caffeinated tea (RR = 0.9, 95% CI 0.4–2.0; \( p = 0.85 \)) or cola (RR = 1.0, 95% CI 0.4–2.4; \( p = 0.95 \)) were not elevated (figure 1). The RRs for coffee consumption did not vary by sex (\( p = 0.13 \)), age (\( p = 0.56 \)), smoking status (\( p = 0.22 \)), physical activity (\( p = 0.44 \)), or stroke etiology (\( p = 0.29 \)). When we stratified by daily intake of caffeinated coffee in the past week, the association between ischemic stroke in the hour after coffee consumption was only apparent among those consuming 1 or fewer cups per day but not for patients who consumed coffee more regularly (\( p \) for trend = 0.002; figure 2).

In a sensitivity analysis using the conservative assumption that all coffee in the past year is only consumed in the morning (6 AM–9 AM), coffee consumption was still associated with an increased risk of ischemic stroke onset (RR = 3.8, 95% CI 2.0–7.0; \( p < 0.001 \)). Among the 304 subjects exposed to coffee in the prior year, 75 subjects were exposed to other potential triggers in the hour prior to stroke onset. Of the 35 people exposed to coffee in the hour prior to stroke onset, 3 were also exposed to vigorous physical activity, 1 experienced feelings of anger, 1 smoked a cigarette, and 1 drank an alcoholic beverage. When we conducted an analysis excluding the 75 people exposed to any potential stroke trigger in the hour prior to stroke onset, the results remained similar. RRs were similar when the sample was restricted to those who did not experience a stroke or MI in the prior year (\( n = 283 \)). On average, subjects reported almost identical levels of coffee consumption in the week preceding the stroke and in the prior year, so the RR did not change when we used each subject’s reported frequency of consumption in the past week to estimate control periods.

**b** At one of the centers, stroke etiology was not determined \( n = 32 \).
DISCUSSION

In this study, we found that coffee consumption was associated with a transient risk of ischemic stroke in the subsequent hour that was 2.0 times higher than the risk during periods with no coffee consumption, and the risk returned to baseline by 2 hours. Our findings are consistent with 2 case-crossover studies on coffee intake and other acute cardiovascular events.9,10 In a study of 503 incident cases of nonfatal myocardial infarction,9 the RR of acute myocardial infarction in the hour after coffee intake was 1.5 (95% CI 1.2–1.9), and the association was particularly strong for those who are only occasional coffee drinkers, those with 3 or more cardiovascular risk factors, and those who lead sedentary lifestyles. A similar study10 reported that the RR of dying from sudden cardiac death within an hour after drinking a cup of coffee was 73% higher (95% CI 1.1–2.7) than periods with no coffee consumption. Similar to the prior study of myocardial infarction,9 we found that the effect of coffee consumption was not significantly different in men vs women, subjects older or younger than 65 years of age, or by smoking status, frequency of habitual physical activity, or stroke etiology.

We did not find an association between consumption of caffeinated tea or cola and ischemic stroke. The lower dose of caffeine in these beverages may account for this difference.17 Evidence from experimental studies indicates that coffee acutely increases circulating concentrations of (nor)epinephrine,2 raises systolic and diastolic blood pressure,3 increases arterial stiffness,3,6 and impairs endothelium-dependent vasodilation.7 Some studies have shown that habitual consumption results in a tolerance to the acute effects of caffeine,18,19 while others have found that some individuals continue to experience these acute effects with each drinking episode20,21 and that the tolerance disappears after 12 hours of abstinence.22 This is consistent with our findings and others,9 indicating that the RR of ischemic stroke in the hour following consumption of caffeinated coffee was higher among people reporting lower levels of habitual coffee consumption.

There have been discrepant findings on the association between habitual coffee intake and ischemic stroke. One study found that total coffee consumption was not associated with an increased stroke risk in men23 and another study found that coffee consumption was associated with an increased risk of ischemic stroke among hypertensive men who reported no previous or current smoking.24 However, others have reported that habitual coffee consumption is associated with a lower risk of ischemic stroke. In the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study of men, smokers who drank 8 or more cups of coffee per day had a 23% lower risk of stroke than those who drank fewer than 2 cups per day.25 Similarly, in the Nurses’ Health Study, women who drank 4 or more cups of coffee per day had a 20% lower risk of stroke than those who did not consume coffee.26 These results are concordant with our finding of no increased risk among those who drink coffee regularly, suggesting that habitual consumption results in a tolerance to the acute effects of caffeine.18,19

There are some limitations to our study that warrant discussion. Based on previous research, our a priori hypothesis was focused on caffeinated coffee consumption so we did not collect information on the coffee type or preparation method or on consumption of decaffeinated beverages. Since the case-crossover design uses subjects as their own controls, there is no variability in traditional risk factors for stroke.11 However, confounding by factors that change over time within individual subjects can occur if other transient risk factors occur during the case period of interest. In a sensitivity analysis using a conservative assumption that all coffee in the past year was consumed in the morning, the results remained significant. Though there may be residual confounding by time of day, this suggests that the findings are not fully explained by the co-occurrence of coffee and the circadian peak in stroke onset. A sensitivity analysis excluding subjects reporting other potential triggers in the hour preceding stroke onset did not materially alter the results. We had limited power to determine whether the effect of coffee consumption varied by clinical characteristics or stroke etiology.

Recall bias may occur if there is systematic error in reporting usual exposure frequency compared...
with exposure during the hour before stroke onset.\textsuperscript{11} If subjects overestimate exposure in the period immediately before the stroke and underestimate exposure in the past year, the RR may be biased upwards. In an effort to minimize reporting bias and to maintain subject confidentiality, efforts were made to ensure the subject’s privacy during the interview. We used a standardized structured interview and subjects were not informed of the duration of the hypothesized case period. If patients whose strokes were triggered by coffee consumption were more likely to participate or had milder strokes than those whose strokes were unrelated to coffee, the apparent RR might be overestimated. The patients we interviewed tended to have milder strokes, as those with aphasia, memory difficulties, or severe strokes leaving them incapacitated or too ill to be interviewed were excluded from the study. Therefore, our results may not be generalizable to subjects presenting with a severe or fatal stroke. However, the RR for recent coffee consumption did not vary by stroke etiology, suggesting that the role of coffee as a stroke trigger does not differ by stroke mechanism and is unlikely to vary by severity.
